<b>(54) Title:</b> GENERATION OF XENOGENEIC ANTIBODIES  <b>(57) Abstract</b>  The subject invention provides non-human mammalian hosts characterized by inactivated endogenous Ig loci and functional human Ig loci for response to an immunogen to produce human antibodies or analogs thereof. The hosts are produced by multiple genetic modifications of embryonic cells in conjunction with breeding. Different strategies are employed for recombination of the human loci randomly or at analogous host loci. Chimeric and transgenic mammals, particularly mice, are provided, having stably integrated large, xenogeneic DNA segments. The segments are introduced by fusion with yeast spheroplasts comprising yeast artificial chromosomes (YACs) which include the xenogeneic DNA segments and a selective marker such as HPRT, and embryonic stem cells.

INTRODUCTIONTechnical Field

20 The field of this invention is the production of  
xenogeneic specific binding proteins in a viable mammalian  
host.

Background

25 The ability to produce transgenic animals has been  
revolutionized with the advent of the ability to culture  
murine embryonic stem cells, and to introduce genetic  
modifications in these cells for subsequent transmission  
to the mouse germline. Thus one has the opportunity to  
30 modify endogenous genes to produce animal strains capable  
of producing novel products by introduction of foreign  
genes into the host, particularly human genes to produce  
xenogeneic binding proteins. The expression of such genes  
in vivo in an animal model may provide for investigation  
35 of the function of the gene, the regulation of gene  
expression, its processing, response to various agents  
and the like. In addition, animals with new phenotypes,

including those that mimic a variety of diseases, may be produced. For example, there is interest in introducing a dominant mutation or complementing a recessive mutation. Depending on the particular gene, the difficulty of achieving the desired mutation will vary greatly. While some gene targets have proven to be relatively amenable to modification, other targets have proven to be extremely resistant to modification.

Because of the opportunity for generating transgenic animals, there is substantial interest in providing new procedures that increase the success of production of transgenic animals. Particularly, where one wishes to introduce large DNA fragments, encompassing hundreds of kilobases, there is substantial concern about the ability to introduce the large fragments in intact form into mammalian cells, the efficiency of integration, the functional capability of the gene(s) present on the fragment and transmission in the germline to the progeny. In addition, such procedures for introduction of large DNA fragments provide for determination of the function of large DNA fragments identified in the ongoing human genome project.

In particular, there is interest in producing xenogeneic specific binding proteins, for example human monoclonal antibodies, in small laboratory animals such as mice. Monoclonal antibodies find use in both diagnosis and therapy. Because of their ability to bind to a specific epitope, they can be uniquely used to identify molecules carrying that epitope or may be directed, by themselves or in conjunction with another moiety, to a specific site for diagnosis or therapy.

Monoclonal antibodies comprise heavy and light chains which join together to define a binding region for the epitope. Each of the chains is comprised of a variable region and a constant region. The constant region amino acid sequence is specific for a particular isotype of the antibody, as well as the host which produces the antibody.

Because of the relationship between the sequence of the constant region and the species from which the antibody is produced, the introduction of a xenogeneic antibody into the vascular system of the host can produce an immune response. Where the xenogeneic antibody is introduced repetitively, in the case of chronic diseases, it becomes impractical to administer the antibody, since it will be rapidly destroyed and may have an adverse effect. There have been, therefore, many efforts to provide a source of syngeneic or allogeneic antibodies. One technique has involved the use of recombinant DNA technology where the genes for the heavy and light chains from a host were identified and the regions encoding the constant region isolated. These regions were then joined to the variable region encoding portion of other immunoglobulin genes from another species directed to a specific epitope.

While the resulting chimeric partly xenogeneic antibody is substantially more useful than using a fully xenogeneic antibody, it still has a number of disadvantages. The identification, isolation and joining of the variable and constant regions requires substantial work. In addition, the joining of a constant region from one species to a variable region from another species may change the specificity and affinity of the variable regions, so as to lose the desired properties of the variable region. Also, there are framework and hypervariable sequences specific for a species in the variable region. These framework and hypervariable sequences may result in undesirable antigenic responses.

It would therefore be more desirable to produce allogeneic antibodies for administration to a host by immunizing the host with an immunogen of interest. For primates, particularly humans, this approach is not practical. The human antibodies which have been produced have been based on the adventitious presence of an available spleen, from a host which had been previously

immunized to the epitope of interest. While human peripheral blood lymphocytes may be employed for the production of monoclonal antibodies, these have not been particularly successful in fusions and have usually led only to IgM. Moreover, it is particularly difficult to generate a human antibody response against a human protein, a desired target in many therapeutic and diagnostic applications. There is, therefore, substantial interest in finding alternative routes to the production of allogeneic antibodies for humans.

SUMMARY OF THE INVENTION

5 Xenogeneic specific binding proteins are produced in a non-human viable host by immunization of the host with an appropriate immunogen.

10 A preferred non-human host is characterized by: (1) being incapable of producing endogenous immunoglobulin heavy chain; (2) being substantially incapable of producing endogenous immunoglobulin light chains; and (3) capable of producing xenogeneic immunoglobulin light and heavy chains to produce a xenogeneic immunoglobulin or immunoglobulin analog. Thus, the host may have an entire endogenous immunoglobulin locus substituted by a portion of, or an entire, xenogeneic immunoglobulin locus, or may have a xenogeneic immunoglobulin locus inserted into a chromosome of the host cell and an inactivated endogenous immunoglobulin region. These various alternatives will be achieved, at least in part, by employing homologous recombination for inactivation or replacement at the immunoglobulin loci for the heavy and light chains.

20 Additionally, novel methods are provided for introducing large segments of xenogeneic DNA of at least 100 kb, particularly human DNA, into host animals, particularly mice, by introducing a yeast artificial chromosome (YAC) containing a xenogeneic DNA segment of at least 100 kb, into an embryonic stem cell for integration into the genome of the stem cell, selection of stem cells comprising the integrated YAC by means of a marker present in the YAC, introduction of the YAC-containing ES cells into embryos and generation of chimeric mice from the embryos. The chimeric animals may be mated to provide animals that are heterozygous for the YAC. The heterozygous animals may be mated to generate progeny homozygous for the integrated YAC.

Figure 14 A, B, C demonstrates the stable retention of yHPRT during in vitro ES cell differentiation and transmission through the mouse germline, as described in Example VI, infra (A: a, b = embryoid bodies; and differentiated cell types: c = blood islands; d = contracting muscle; e = neuronal cells; f = neural tubules formed by ESY clones; B: Southern blot analysis of DNA extracted from differentiated ESY 5-2, 3-6, 8-5 and 8-6 (20  $\mu$ g) and yHPRT in AB1380 (40 ng) using a = human Alu probe; b = yeast Ty sequences; C: Southern blot analysis of tail DNA (20  $\mu$ g) from 2 agouti offspring (4-2 and 4-3) derived from ESY chimeric male 394/95-2 using a = human Alu and b = Ty sequences; shorter exposures (12 hr) of 8-6 and yHPRT probed with Ty are shown (II)).

Figure 15 A and B are a photograph of an electrophoresis gel showing the expression of the human HPRT gene in various mouse tissues, as described in Example VI, infra (15 A = detection of human HPRT mRNA using reverse transcription-PCR in ES, ESY 3-1 and Hut 78 cells, spleen and liver from control mice or ESY 4-3 agouti offspring; 15 B = detection of mouse  $\gamma$ -interferon receptor mRNA by RT-PCR in samples from 15 A; M = size marker).

Figure 16 is a diagram of the human immunoglobulin heavy chain locus, and a human heavy chain replacement YAC vector, as described in Example VII, infra.

Figure 17 is a diagram of a mouse breeding scheme, as described in Example VIII, infra.

Figure 18 depicts the genotypes of some of the host animals produced by the methods of the invention.

DESCRIPTION OF SPECIFIC EMBODIMENTS

Novel transgenic non-human hosts, particularly mammalian hosts, usually murine, are provided, where the host is capable of mounting an immune response to an immunogen, where the response produces antibodies having xenogeneic, particularly primate, and more particularly human, constant and/or variable regions or such other effector peptide sequences of interest. By "transgenic" is meant an animal that contains a genetically engineered modification, particularly, as to this invention, the introduction of a human immunoglobulin gene, in all of its cells. The hosts are characterized by being capable of producing xenogeneic immunoglobulins or analogs thereof as a result of inactivation of the endogenous immunoglobulin subunit encoding loci and introduction of xenogeneic DNA, for example DNA encoding human immunoglobulin. The modifications may retain at least a portion of the xenogeneic constant regions which provide for assembly of the variable region binding site bonded at the C-terminus to a functional peptide. The functional peptide may take many forms or conformations and may serve as an enzyme, growth factor, binding protein, ligand, cytokine, effector protein, chelating proteins, etc. The antibodies may be of any isotype, e.g., IgA, D, E, G or M or subtypes within the isotype.

In a first strategy, as individual steps, the xenogeneic, e.g. human, heavy and light chain immunoglobulin genes are introduced into the host germ line (e.g. sperm or oocytes) and in separate steps the corresponding host genes are rendered non-functional by inactivation using homologous recombination. Human heavy and light chain immunoglobulin genes are reconstructed in an appropriate eukaryotic or prokaryotic microorganism and the resulting DNA fragments can be introduced into the appropriate host, for example into the pronuclei of fertilized mouse oocytes or embryonic stem cells.

Inactivation of the endogenous host immunoglobulin loci is achieved by targeted disruption of the appropriate loci by homologous recombination in the host cells, particularly embryonic stem cells or pronuclei of fertilized mouse oocytes. The targeted disruption can involve introduction of a lesion or deletion in the target locus, or deletion within the target locus accompanied by insertion into the locus, for example, insertion of a selectable marker. In the case of embryonic stem cells, chimeric animals are generated which are derived in part from the modified embryonic stem cells and are capable of transmitting the genetic modifications through the germ line. The mating of hosts with introduced human immunoglobulin loci to strains with inactivated endogenous loci will yield animals whose antibody production is purely xenogeneic, e.g. human.

In a second, alternative strategy, at least portions of the human heavy and light chain immunoglobulin loci are used to directly replace the corresponding endogenous immunoglobulin loci by homologous recombination in embryonic stem cells. This results in simultaneous inactivation and replacement of the endogenous immunoglobulin. This is followed by the generation of chimeric animals in which the embryonic stem cell-derived cells can contribute to the germ line.

These strategies are based on the known organization of the immunoglobulin chain loci in a number of animals, since the organization, relative location of exons encoding individual domains, and location of splice sites and transcriptional elements is understood to varying degrees. In the human, the immunoglobulin heavy chain ( $IgH_{hu}$ ) locus is located on chromosome 14. In the 5' - 3' direction of transcription, the locus comprises a large cluster of variable region genes ( $V_H$ ), the diversity (D) region genes, followed by the joining ( $J_H$ ) region genes and the constant ( $C_H$ ) gene cluster. The size of the locus is estimated to be about from 1,500 to about 2,500

kilobases (kb). During B-cell development, discontinuous gene segments from the germ line IgH locus are juxtaposed by means of a physical rearrangement of the DNA. In order for a functional heavy chain Ig polypeptide to be produced, three discontinuous DNA segments, from the V<sub>H</sub>, D, and J<sub>H</sub> regions must be joined in a specific sequential fashion; first D to J<sub>H</sub> then V<sub>H</sub> to DJ<sub>H</sub>, generating the functional unit V<sub>H</sub>DJ<sub>H</sub>. Once a V<sub>H</sub>DJ<sub>H</sub> has been formed, specific heavy chains are produced following transcription of the Ig locus, utilizing as a template the specific V<sub>H</sub>DJ<sub>H</sub>C<sub>H</sub> unit comprising exons and introns.

There are two loci for immunoglobulin light chains (IgL), the kappa locus on human chromosome 2 and the lambda locus on human chromosome 22. The organization of the IgL loci is similar to that of the IgH locus, except that the D region is not present. Following IgH rearrangement, rearrangement of a light chain locus is similarly accomplished by V<sub>L</sub> to J<sub>L</sub> joining of the kappa or lambda chain. The sizes of the lambda and kappa loci are each approximately 1000 kb to 2000 kb. Expression of rearranged IgH and an Igκ or Igλ light chain in a particular B-cell allows for the generation of antibody molecules.

In order to isolate, clone and transfer the IgH<sub>hu</sub> locus, a yeast artificial chromosome or "YAC" may be employed. A YAC carrying the xenogeneic DNA may be introduced into ES cells or oocytes by a variety of methods, including yeast spheroplast: ES cell fusion, microinjection and lipofection. The YAC will integrate randomly (i.e. non-homologously) into the host genome. If yeast spheroplast:ES cell fusion is employed to introduce a YAC carrying xenogeneic DNA into ES host cells, then two or more YACs in a single yeast host cell may be introduced simultaneously into the same host ES cell. The advantage of this approach is that multiple YACs each containing xenogeneic DNA, for example human heavy and light chain immunoglobulin loci, can be introduced

into a single chromosome in a host cell. This eliminates the need for breeding of animals containing individual human Ig genes in order to generate a host capable of producing fully human immunoglobulins. For example, a strain of yeast containing a single YAC is targeted with a vector such as pLUTO (described infra) to introduce a mammalian selectable marker such as HPRT, and a yeast selectable marker such as LYS2 into an arm of the YAC. Chromosomal DNA from the targeted strain is then used to transform a second, usually haploid, lys2 mutant yeast strain containing a second, different YAC. Lys+ colonies are then analyzed by pulsed-field gel electrophoresis (PFGE) to identify clones harboring the two YACs and to confirm that they are unaltered in size. Additional YACs with different selectable markers, for example ADE2 (if the host is an ade2 mutant), can subsequently be added by transformation. Alternatively, a YAC-containing strain of yeast is targeted with a vector such as pLUTO to introduce a mammalian selectable marker (e.g. HPRT), as above, and then mated to a second YAC-containing strain of opposite mating type. The presence of the two YACs is then confirmed in the diploid yeast cells as described above. The diploid yeast strain is used directly for fusion or put through meiosis and ascosporeogenesis (sporulation) using standard procedures. The meiotic products are then screened to identify a haploid clone containing the two YACs. With either approach described above, the second YAC can be targeted with HPRT or another selectable marker prior to introduction of the first YAC. Also, if each YAC contains a different yeast selectable marker, maintenance of both YACS during strain propagation may be genetically selected. Fusion with ES cells is then carried out in the same manner as with yeast cells containing a single YAC. Because many yeast chromosomes may integrate along with the YAC, it is expected that a substantial portion of ES clones expressing the mammalian selectable marker present in one YAC (e.g. HAT<sup>R</sup> clones

if the YAC marker is HPRT, and the ES cells are HPRT-), will have integrated both YACs. Methods such as Southern analysis and/or PCR may be used to identify such clones, and Southern analysis employing pulsed-field gel electrophoresis used to characterize the extent of YAC integration.

The entire IgH<sub>h</sub> locus can be contained within one or a few YAC clones along with a mammalian marker such as Neo, HPRT, GPT,  $\beta$ -gal, etc. The same is true for the Ig light chain loci. Reconstitution of intact germ line Ig loci by homologous recombination between YACs with overlapping regions of homology can be achieved in yeast.. In this manner, the isolation of DNA fragments encoding the human Ig chain is obtained. Alternatively, one can directly clone an intact germline locus in a single YAC.

In order to obtain a broad spectrum of high affinity antibodies, it is not necessary that one include the entire V region. Various V region gene families are interspersed within the V region cluster in humans. Thus, by obtaining a subset of the known V region genes of the human heavy and light chain Ig loci (Berman et al., EMBO J. (1988) 7:727-738) rather than the entire complement of V regions, the transgenic host may be immunized and be capable of mounting a strong immune response and provide high affinity antibodies. In this manner, relatively small DNA fragments of the chromosome may be employed. For example, a reported 670 kb fragment of the IgH<sub>h</sub> locus is contained on a NotI-NotI restriction fragment, which would serve to provide a variety of V regions (Berman et al., supra). Increased diversity is also provided by recombination with the various D and J regions and somatic mutation.

To render the host immunoglobulin loci non-functional, homologous recombination may be employed, where DNA is introduced at the endogenous host immunoglobulin heavy chain and light chain loci which inhibits the production of endogenous immunoglobulin.

Because there are two heavy chain alleles and two light chain loci, kappa and lambda, each with two alleles, although one may choose to ignore the lambda loci, there will have to be multiple transformations which result in inactivation of each of the alleles. Homologous recombination may be employed to functionally inactivate each of the loci, by introduction of the homologous DNA via a construct that can disrupt or delete the target locus into embryonic stem cells, followed by introduction of the modified cells into recipient blastocysts. Subsequent breeding allows for germ-line transmission of the inactivated locus. One can therefore choose to breed heterozygous offspring and select for homozygous offspring from the heterozygous parents.

In the second, alternative strategy described above, the number of steps may be reduced by providing at least a fragment of the human immunoglobulin locus within the construct used for homologous recombination with the analogous endogenous immunoglobulin, so that the human locus is substituted for at least a part of the host immunoglobulin locus, with resulting inactivation of the host immunoglobulin subunit locus. Of particular interest is the use of transformation for a single inactivation, followed by breeding of the heterozygous offspring to produce a homozygous offspring. Where the human locus is employed for substitution or insertion into the host locus for inactivation, the number of transformations may be limited to three transformations and as already indicated, one may choose to ignore the less used locus and limit the transformations to two transformations. Alternatively, one may choose to provide for inactivation as a separate step for each locus, employing embryonic stem cells from offspring which have previously had one or more loci inactivated. In the event that only transformation is used and the human locus is integrated into the host genome in random fashion, a total of eight or more transformations may be required.

For inactivation, any lesion in the target locus resulting in the prevention of expression of an immunoglobulin subunit of that locus may be employed. Thus, the lesion may be in a region comprising enhancers, e.g., a 5' or 3' enhancer, or intron, in the V, J or C regions, and with the heavy chain, the opportunity exists in the D region, or combinations thereof. The important factor is that Ig germ line gene rearrangement is inhibited, or a functional message encoding the endogenous immunoglobulin cannot be produced, either due to failure of transcription, failure of processing of the message, or the like. Such a lesion may take the form of a deletion in the target gene, an insertion of a foreign gene, a combination of an insertion and deletion, or a replacement using xenogeneic sequences with or without introduction of a deletion in the endogenous gene.

Preferably, when one is interested in inactivating the immunoglobulin subunit locus, the lesion will be introduced into one or more of the exons contained in the immunoglobulin subunit locus, for example in the constant or J region of the locus. Thus, one produces a targeting construct which lacks functional exons in this region and may comprise the sequences adjacent to and upstream and/or downstream from the J and/or C region or comprises all or part of the region with an inactivating insertion in the J or C exons. The insertion may be 50 bp or more, where such an insertion results in disruption of formation of a functional mRNA. Desirably, usually at least about 75% of the exon sequence, preferably at least about 90% of the exon sequence, is deleted.

Desirably, a marker gene is used in the targeting construct to replace the deleted sequences. Various markers may be employed, particularly those which allow for positive selection. Of particular interest is the use of G418 resistance, resulting from expression of the gene for neomycin phosphotransferase ("neo").

In the targeting construct, upstream and/or downstream from the target gene, may be a gene which provides for identification of whether a homologous double crossover has occurred (negative selection). For this purpose, the Herpes simplex virus thymidine kinase gene may be employed, since cells expressing the thymidine kinase gene may be killed by the use of nucleoside analogs such as acyclovir or gancyclovir, by their cytotoxic effects on cells that contain a functional HSV-tk (Mansour et al., Nature 336:348-352 (1988)). The absence of sensitivity to these nucleoside analogs indicates the absence of the HSV-thymidine kinase gene and, therefore, where homologous recombination has occurred, that a double crossover has also occurred.

While the presence of the marker gene in the genome will indicate that integration has occurred, it will still be necessary to determine whether homologous integration has occurred. This can be achieved in a number of ways. For the most part, DNA analysis by Southern blot hybridization will be employed to establish the location of the integration. By employing probes for the insert and the sequences at the 5' and 3' regions flanking the region where homologous integration would occur, one can demonstrate that homologous targeting has occurred.

PCR may also be used with advantage in detecting the presence of homologous recombination. PCR primers may be used which are complementary to a sequence within the targeting construct and complementary to a sequence outside the construct and at the target locus. In this way, one can only obtain DNA molecules having both the primers present in the complementary strands if homologous recombination has occurred. By demonstrating the expected size fragments, e.g. using Southern blot analysis, the occurrence of homologous recombination is supported.

The targeting construct may further include a replication system which is functional in the host cell. For the most part, these replication systems will involve

viral replication systems, such as Simian virus 40, Epstein-Barr virus, polyoma virus, papilloma virus, and the like. Various transcriptional initiation systems may be employed, either from viruses or from mammalian genes, such as SV40, metallathionein-I and II genes,  $\beta$ -actin gene, adenovirus early and late genes, phosphoglycerate kinase gene, RNA polymerase II gene, or the like. In addition to promoters, wild-type enhancers may be employed to further enhance the expression of the marker gene.

In preparing the targeting constructs for homologous recombination, a replication system for procaryotes, particularly E. coli, may be included for preparing the targeting construct, subcloning after each manipulation, analysis such as restriction mapping or sequencing, expansion and isolation of the desired sequence. In the case of the replacement strategy, where the xenogeneic DNA insert is large, generally exceeding about 50 kbp, usually exceeding 100 kbp, and usually not more than about 1000 kbp, a yeast artificial chromosome (YAC) may be used for cloning of the targeting construct.

Once a targeting construct has been prepared and any undesirable sequences removed, e.g., procaryotic sequences, the construct may now be introduced into the target cell, for example an ES cell. Any convenient technique for introducing the DNA into the target cells may be employed. Techniques include protoplast fusion, e.g. yeast spheroplast:cell fusion, lipofection, electroporation, calcium phosphate-mediated DNA transfer or direct microinjection.

After transformation or transfection of the target cells, target cells may be selected by means of positive and/or negative markers, as previously indicated, neomycin resistance and acyclovir or gancyclovir resistance. Those cells which show the desired phenotype may then be further analyzed by restriction analysis, electrophoresis, Southern analysis, PCR, or the like. By identifying fragments which show the presence of the lesion(s) at the

target locus, one can identify cells in which homologous recombination has occurred to inactivate a copy of the target locus.

5       The above described process may be performed first  
to inactivate a heavy chain locus in an embryonic stem  
cell whereby the cells are microinjected into host  
blastocysts which develop into a chimeric animal. The  
chimeric animals are bred to obtain heterozygous hosts.  
Then, by breeding of the heterozygous hosts, a homozygous  
10       host may be obtained or embryonic stem cells may be  
isolated and transformed to inactivate the second IgH  
locus, and the process repeated until all the desired loci  
have been inactivated. Alternatively, the light chain  
locus may be the first to be inactivated. For complete  
15       elimination of the ability to produce light chain  
immunoglobulin, it is desirable to inactivate both the  
lambda and the kappa light chain immunoglobulin loci.  
At any stage, the xenogeneic loci may be introduced.

20       As already indicated, the target locus may be  
substituted with the analogous xenogeneic locus. In this  
way, the xenogeneic locus will be placed substantially  
in the same region as the analogous host locus, so that  
any regulation associated with the position of the locus  
will be substantially the same for the xenogeneic  
25       immunoglobulin locus. For example, by isolating the  
variable region of the human IgH locus (including V, D,  
and J sequences), or portion thereof, and flanking the  
human locus with sequences from the murine locus,  
preferably sequences separated by at least about 5 kbp,  
30       in the host locus, preferably at least about 10 kbp in  
the host locus, one may insert the human fragment into  
this region in a recombinational event(s), substituting  
the human immunoglobulin locus for the endogenous variable  
region of the host immunoglobulin locus. In this manner,  
35       one may disrupt the ability of the host to produce an  
endogenous immunoglobulin subunit, while allowing for the  
promoter of the human immunoglobulin locus to be activated

by the host enhancer and regulated by the regulatory system of the host.

5 In order to provide for the production of xenogeneic binding proteins in a host, it is necessary that the host be competent to provide the necessary enzymes and other factors involved with the production of antibodies, while lacking competent endogenous genes for the expression of heavy and light subunits of immunoglobulins. Thus, those enzymes and other factors associated with germ line rearrangement, splicing, somatic mutation, and the like  
10 will be functional in the host. What will be lacking is a functional natural region comprising the various exons associated with the production of endogenous immunoglobulin.

15 The integration of introduced xenogeneic DNA may be random or homologous depending on the particular strategy to be employed. Thus, by using transformation, using repetitive steps or in combination with breeding, transgenic animals may be obtained which are able to produce xenogeneic binding proteins in the substantial  
20 absence of light or heavy endogenous immunoglobulin. By transformation is intended any technique for introducing DNA into a viable cell, such as conjugation, PEG-mediated cell fusion, transformation, transfection, transduction, electroporation, lipofection, biolistics, or the like.

25 Once the xenogeneic loci, have been introduced into the host genome, either by homologous recombination or random integration, and host animals have been produced with the endogenous immunoglobulin loci inactivated by appropriate breeding of the various transgenic animals  
30 or animals derived from chimeric animals, one can produce a host which lacks the native capability to produce endogenous immunoglobulin, but has the capacity to produce xenogeneic immunoglobulins with at least a significant portion of the repertoire of the xenogeneic source.

35 The functional inactivation of the two copies of each of the three host Ig loci (heavy, kappa and lambda), where

the host then contains the human IgH and the human Ig kappa and/or lambda loci would allow for the production of purely human antibody molecules without the production of host or host/human chimeric antibodies. Such a host strain, by immunization with specific antigens, would respond by the production of murine B-cells producing specific human antibodies, which B-cells could be fused with murine myeloma cells or be immortalized in any other manner for the continuous stable production of human monoclonal antibodies. Methods are well known in the art for obtaining continuous stable production of monoclonal antibodies.

The subject methodology and strategies need not be limited to producing complete immunoglobulins, but provides the opportunity to provide for regions joined to a portion of the constant region, e.g., C<sub>H1</sub>, C<sub>H2</sub>, C<sub>H3</sub>, or C<sub>H4</sub>, or combination thereof. Alternatively, one or more of the exons of the C<sub>H</sub> and C<sub>κ</sub> or C<sub>λ</sub> regions may be replaced or joined to a sequence encoding a different protein, such as an enzyme, e.g., plasminogen activator, superoxide dismutase, etc.; toxin, e.g., ricin, abrin, diphtheria toxin, etc.; growth factor; cytotoxic agent, e.g., TNF; receptor ligand, or the like. See, for example, WO 89/07142; WO 89/09344; and WO 88/03559. By inserting the protein of interest into a constant region exon and providing for splicing of the variable region to the modified constant region exon, the resulting binding protein may have a different C-terminal region from the immunoglobulin. By providing for a stop sequence with the inserted gene, the protein product will have the inserted protein as the C-terminal region. If desired, the constant region may be entirely substituted by the other protein, by providing for a construct with the appropriate splice sites for joining the variable region to the other protein.

The B-cells from the transgenic host producing immunoglobulin or immunoglobulin analog may be used for

fusion to a murine myeloid cell to produce hybridomas or  
immortalized by other conventional process, e.g.,  
transfection with oncogenes. These immortalized cells may  
then be grown in continuous culture or introduced into  
the peritoneum of a compatible host for production of  
ascites.

The subject invention provides for the production  
of polyclonal human anti-serum or human monoclonal  
antibodies or antibody analogs. Where the mammalian host  
has been immunized with an immunogen, the resulting human  
antibodies may be isolated from other proteins by using  
an affinity column, having an Fc binding moiety, such as  
protein A, or the like.

The invention includes the following embodiments of  
non-human hosts (see also Figure 18):

I. Animals heterozygous for an inactive endogenous  
light chain immunoglobulin gene (homozygous animals are  
obtained by interbreeding);

II. Animals heterozygous for an inactive endogenous  
heavy chain immunoglobulin gene (homozygous animals are  
obtained by interbreeding);

III. Animals homozygous for functional endogenous  
light and heavy chain immunoglobulin genes and hemizygous  
for (i.e. containing one copy of) foreign, preferably  
human, heavy chain immunoglobulin genes (homozygous  
animals are obtained by interbreeding);

IV. Animals homozygous for functional endogenous  
light and heavy chain immunoglobulin genes and hemizygous  
for foreign, preferably human, light chain immunoglobulin  
genes (homozygous animals are obtained by interbreeding);

V. Animals heterozygous for inactive endogenous  
heavy and light chain immunoglobulin genes obtained by  
crossbreeding animals of category I with animals from  
category II (homozygous animals are obtained by  
interbreeding);

5 VI. Animals heterozygous for inactive endogenous heavy and light chain immunoglobulin genes and hemizygous for foreign, preferably human, heavy chain immunoglobulin genes obtained by crossbreeding animals of category III with animals from category V (animals homozygous for the inactive endogenous loci and homo- or hemizygous for the foreign gene are obtained by interbreeding);

10 VII. Animals heterozygous for inactive endogenous heavy and light chain immunoglobulin genes and hemizygous for foreign, preferably human, light chain immunoglobulin genes obtained by crossbreeding animals of category IV with animals from category V (animals homozygous for the inactive endogenous loci and homo- or hemizygous for the foreign gene are obtained by interbreeding);

15 VIII. Animals homozygous or heterozygous for inactive endogenous heavy and light chain immunoglobulin genes and hemizygous for foreign, preferably human, light and heavy chain immunoglobulin genes, obtained by crossbreeding animals of category VI and VII (animals homozygous for the inactive endogenous loci and homo- or hemizygous for the foreign gene are obtained by interbreeding);

20 In a preferred embodiment, the homozygous animals of category VIII are used to produce human antibodies.

25 IX. Animals homozygous for functional endogenous heavy and light chain immunoglobulin genes and hemizygous for foreign, preferably human, heavy and light chain immunoglobulin genes, obtained by crossbreeding animals of category III and IV (homozygous animals are obtained by interbreeding);

30 X. Animals heterozygous for an inactive endogenous heavy chain immunoglobulin gene and hemizygous for foreign, preferably human, heavy and light chain immunoglobulin genes, obtained by crossbreeding animals of category II and IX (animals homozygous for the inactive endogenous loci and homo- or hemizygous for the foreign gene are obtained by interbreeding).

XI. Animals heterozygous for an inactive endogenous light chain immunoglobulin gene and hemizygous for foreign, preferably human, heavy and light chain immunoglobulin genes, obtained by crossbreeding animals of category I and IX (animals homozygous for the inactive endogenous loci and homo- or hemizygous for the foreign gene are obtained by interbreeding).

The invention also provides a method for introducing large continuous, xenogeneic DNA sequences into a non-human, e.g. mammalian, host. Usually, the sequences will be at least 100 kb, more usually at least about 200 kb, generally ranging from about 200 to 1000 kb. Thus, one may wish to transfer a locus of interest, such as the immunoglobulin locus, T-cell receptor locus, major histocompatibility locus; regions of an xenogeneic chromosome, which may include one or more genes of interest, which may or may not have been characterized, such as the Low Density Lipoprotein (LDL) receptor, Apolipoprotein (Apo) B, Apo E, cystic fibrosis transmembrane conductor regulator, dystrophin, or regions of xenogeneic chromosomes that may be involved in partial chromosome trisomy (e.g. chromosomes 21, 7 and 10); and viruses. The DNA may comprise wild type or defective genes for studying a variety of diseases by creating dominant mutations or complementing recessive mutations, for example the LDL receptor and Apo B genes can be introduced for the study of hypercholesterolemia, hyperlipoproteinemia and atherosclerosis, Factor VIII or IX can be introduced for hemophilia, cystic fibrosis transmembrane conductance regulator can be introduced for cystic fibrosis and the dystrophin gene for muscular dystrophy. The xenogeneic DNA to be introduced using a YAC is from a mammalian source, particularly primates, more particularly human, other vertebrates or invertebrates and the like. One can thus impart numerous novel capabilities to the host, create genetic responses related to the xenogeneic source of the DNA, provide for

the production of antibodies, provide for specific combinations of transcription factors, provide for metabolic systems, introduce dominant mutations or complement recessive mutations. The xenogeneic DNA may be modified when present in a YAC. Because homologous recombination is efficient in yeast, giving a high ratio of site-specific integration of homologous DNA, where the homologous DNA flanks other DNA of interest, one is able to modify the xenogeneic DNA before introduction into an ES cell. In this way, one can introduce defective genes into the host which express defective proteins to mimic diseased states of the xenogeneic host, to study various mechanisms of the interaction of defective proteins with other xenogeneic proteins or endogenous proteins, or to study genes or gene systems.

In general, to transfer large DNA segments, as described in detail herein, YACs are employed which comprise a yeast centromere, an origin of replication and telomeres bounding the DNA of interest. Various centromeres or telomeres may be used, particularly the centromeres from yeast chromosomes 4 and 5. The YAC has a marker which allows for selection or screening of cells into which the YAC becomes integrated. Not all markers allow for efficient selection. Particularly, the HPRT gene, more particularly human HPRT, is found to permit efficient selection of HPRT-deficient ES cells carrying the YAC. Other known selectable or screenable markers include hygromycin, neomycin,  $\beta$ -gal, and GPT. The ES cell may be derived from any non-human host, from which ES cells are available, and can be expanded in culture, which remain viable and functional, for which a marker for selection exists, and where the ES cell can be introduced into an embryo and can repopulate the host, including the germline. For the most part this capability has been established with rodents, e.g. mice and rats, and to a lesser extent with guinea pigs. Mice have been used for the production of antibodies or B-lymphocytes for

immortalization for the production of antibodies. Because mice are easy to handle, can be produced in large quantities, and are known to have an extensive immune repertoire, mice will usually be the animal of choice.

5 As other species of ES cells become available, these may also be employed in accordance with the subject invention. Of particular interest will be small laboratory animals, or domestic animals particularly rodents, including mice, rats, rabbits, cows, pigs, hamsters, horses, dogs, sheep

10 and guinea pigs, or birds such as chickens, turkeys, etc. The ES cells may have one or more mutations, for example lacking a particular activity. Of particular interest in this invention are ES cells that are deficient in HPRT. In addition, fertilized eggs of certain species may find

15 use in accordance with the invention.

The YAC may be obtained by screening existing human YAC libraries such as those available from the Centre d'Etude du Polymorphisme Human (C.E.P.H.), Paris, France, and Washington University, St. Louis, MO, using standard

20 procedures. Alternatively, the YAC is readily prepared as described in detail herein, by joining the yeast flanking segments comprising one arm with a centromere and telomere and another with a telomere together with the DNA of interest. Usually there will also be one or

25 more markers present that allow for selection in the yeast host cells. For yeast selection, of particular interest are markers which complement mutations of the yeast host, such as genes involved in the production of amino acids, purines or pyrimidines, URA3, TRP1, LYS2, ADE2 on the YAC

30 to complement ura3, trp1, lys2 and Ade2 mutations in the host. By providing for complementation, for the most part only yeast cells carrying the entire YAC will be able to survive in a selective medium. In addition to genetic verification that both YAC arms have been retained, it

35 is desirable to confirm the integrity of the YAC using a method such as pulsed-field gel electrophoresis.

Those yeast hosts carrying the YAC may then be used as a source of the YAC for introduction into the ES cell. Transfer of the YAC is efficiently achieved by preparing yeast spheroplasts in accordance with conventional ways.

5 By degrading the outer wall, under mild conditions, in an isotonic medium, spheroplasts are produced in high yield. Exponentially growing ES cells are protease-treated, e.g. trypsinized, and combined with the spheroplasts. Conveniently, a pellet of yeast spheroplasts

10 can be prepared and the ES cells are spun with the pellet and exposed to a fusogenic agent such as PEG for 1-2 minutes. The cells are then resuspended and incubated in appropriate serum-free medium. The cells are then plated onto feeder cells, followed by selection in

15 accordance with the selective marker. For the HPRT gene, HAT medium may be employed for selection. Surviving fusion colonies are then, picked, expanded and analyzed. Analysis may be performed by restriction enzyme analysis, combined with Southern blotting or pulsed-field gel

20 electrophoresis, or by the polymerase chain reaction (PCR), employing appropriate primers, at least one of which is complementary to the DNA insert, and probing with repetitive sequences present in the xenogeneic DNA, such as Alu, for detection of human DNA sequences. Ty, Y',

25 rDNA, delta sequences are used to probe for for yeast sequences. Probes for YAC ends are used to confirm integrity of the YAC. Those cells that demonstrate the intact or substantially intact YAC DNA integrated into the host genome are then used in the next steps. In some

30 clones, only a portion or little or none of the yeast DNA becomes integrated into the mouse genome. The integrated yeast DNA ranges from more than about 90% of the original yeast genome to less than about 10% .

In a preferred embodiment, efficient production of

35 transgenic non-human hosts is provided using a process which integrates large, at least 100 kb, xenogeneic DNA fragments, in substantially intact form, into a host

embryonic stem (ES) cell or fertilized egg (zygote). The introduction of the xenogeneic DNA is efficiently achieved by fusion of the ES cell with yeast spheroplasts that contain YACs carrying the 100 kb DNA and a selectable marker, under conditions allowing for integration of the YAC DNA containing the marker into the ES cell genome, or by transfection of a purified YAC into ES cells. ES cells comprising the YAC integrated into the genome are then selected by means of the marker, which is functional in the ES cell. For example, the hypoxanthine phosphoribosyl transferase (HPRT) gene may be used as a marker in HPRT deficient (HPRT-) ES cells. For producing animals from embryonic stem cells, after transformation, the cells may be plated onto a feeder layer in an appropriate medium, e.g. fetal bovine serum enhanced DMEM. The ES cell may have a single targeted locus (heterozygous), or may be manipulated by the process of homogenotization to have both loci targeted (homozygous). The process of homogenotization (formation of homozygotes) uses selective pressure to grow out those cells which have the gene targeting event on both chromosomes. Cells containing the two targeted alleles may be detected by employing a selective medium and after sufficient time for colonies to grow, colonies may be picked and analyzed for the occurrence of integration or homologous recombination. As described previously, the PCR may be used, with primers within or outside of the construct sequence, but at the target locus.

Those colonies which show homologous recombination may then be used for embryo manipulation and blastocyst injection. The selected ES cells are then introduced into embryos, by microinjection or other means, into the appropriate host. For example, murine blastocysts may be obtained from female animals by flushing the uterus 3.5 days after ovulation. The modified ES cells are then trypsinized and at least 1 and up to 15 cells may be injected into the blastocoel of the blastocyst. After

injection, at least 1 and no more than about 10 of the blastocysts are returned to each uterine horn of pseudo-pregnant females. The females proceed to term and the resulting chimeric animals can be analyzed for the presence of the YAC in their somatic cells. By "chimeric" is meant an animal that carries cells derived from more than one source, e.g. from the host and another animal. For example, in the present invention a chimeric murine animal contains a genetically engineered modification, particularly a human gene, in some of its cells, e.g. in cells that develop from the modified embryonic stem cells. The presence of the integrated YAC in chimeric hosts that are generated is then analyzed. The chimeric hosts are evaluated for germline transmission of the ES cell genome by mating, for example chimeric mice are mated with C57BL/6J mice. Chimeric hosts may be bred with non-chimeric hosts, either syngeneic or allogeneic, to screen for chimeras that carry the YAC in their germ cells. Offspring that are heterozygous for the genetic modification are then interbred to produce progeny that are homozygous for the modification, stably transmitting the functioning YAC construct to their progeny.

The method of the invention for introduction of large xenogeneic DNA segments into a non-human host, particularly a rodent and usually a murine animal, provides for stable integration of the DNA. Genes in the inserted DNA are found to be functional and the resulting chimeric hosts are able to provide for germline transmission of the integrated DNA. After breeding of the chimeric host, transgenic heterozygous hosts are produced and are mated to produce a homozygous animal that may be used for a wide variety of purposes, including production of products, such as binding proteins, for example immunoglobulins, for screening of various drugs, for gene therapy, for example to complement for recessive genetic disorders, to study various diseases, to study

the function and regulation of poorly mapped large DNA fragments.

The following examples are offered by way of illustration and not by way of limitation.

5

## EXPERIMENTAL

### EXAMPLE I

#### I. Inactivation of the mouse heavy chain J ( $J_H$ ) genes

##### 10 A. Construction of the targeting inactivation vector

A 6.4 kb EcoRI fragment, containing the mouse heavy chain J genes and flanking sequences, is cloned from a Balb/c mouse embryo genomic library using the probes described in Sakano *et al.* (1981), *Nature* 290:562-565. This fragment (mDJ) is inserted into EcoRI-digested pUC19 plasmid (pmDJ). A 2.9 Kb fragment, containing the 4 J genes, is deleted by XhoI-ScaI digestion (pmD $\delta$ JNeo, see Figure 1). An 1150 bp XhoI-BamHI fragment, containing a neomycin-resistance gene driven by the Herpes simplex virus thymidine kinase gene (HSV-tk) promoter and a polyoma enhancer is isolated from pMC1Neo (Thomas and Capecchi (1987), *Cell*, 51, 503-512). A synthetic adaptor is added onto this fragment to convert the BamHI end into a ScaI end and the resulting fragment is joined to the XhoI-ScaI pmD $\delta$ J to form the inactivation vector (pmD $\delta$ J.Neo) in which the 5' to 3' orientation of the neomycin and the heavy chain promoters is identical. This plasmid is linearized by NdeI digestion before transfection to ES cells. The sequences driving the homologous recombination event are 3 kb and 0.5 kb fragments, located 5' and 3' to the neomycin gene, respectively.

##### B. Culturing, Electroporation and Selection of ES Cells

35 The ES cell line E14TG2a (Hooper *et al.* (1987), *Nature*, 326:292-295) is cultured on mitomycin treated primary embryonic fibroblast-feeder layers essentially

as described (Doetschman et al. (1985), J. Embryol. Exp. Morphol. 87:27-45). The embryonic fibroblasts are prepared from embryos from C57BL/6 females that are mated 14 to 17 days earlier with a male homozygous for a neomycin transgene (Gossler et al. (1986), PNAS 83:9065-9069). These cells are capable of growth in media containing G418. Electroporation conditions are described by (Boggs et al. (1986), Ex. Hematol. (NY) 149:988-994). ES cells are trypsinized, resuspended in culture media at a concentration of  $4 \times 10^7$ /ml and electroporated in the presence of the targeting DNA construct at a concentration of 12nM in the first experiment and 5nM DNA in the second. A voltage of 300 V with a capacitance of 150-250  $\mu$ F is found optimal with an electroporation cell of 5 mm length and 100 mm<sup>2</sup> cross-section.  $5 \times 10^6$  electroporated cells are plated onto mitomycin-treated fibroblasts in 100 mm dishes in the presence of Dulbecco's modified Eagle's media (DMEM) supplemented with 15% fetal bovine serum (FBS) and 0.1 mM 2-mercaptoethanol. The media is replaced 24 hrs after electroporation with media containing 200  $\mu$ g/ml G418.

ES colonies resulting 10-14 days after electroporation are picked with drawn out capillary pipettes for analysis using PCR. Half of each picked colony is saved in 24-well plates already seeded with mitomycin-treated feeder cells. The other halves, combined in pools of 3-4, are transferred to Eppendorf tubes containing approximately 0.5 ml of PBS and analyzed for homologous recombination by PCR. Conditions for PCR reactions are essentially as described (Kim and Smithies (1988), Nucleic Acids Res. 16:8887-8893). After pelleting, the ES cells are resuspended in 5  $\mu$ l of PBS and are lysed by the addition of 55  $\mu$ l of H<sub>2</sub>O to each tube. DNases are inactivated by heating each tube at 95°C for 10 min. After treatment with proteinase K at 55°C for 30 min, 30  $\mu$ l of each lysate is transferred to a tube containing 20  $\mu$ l of a reaction mixture including PCR

buffer: 1.5  $\mu$ g of each primer, 3U of Taq polymerase, 10% DMSO, and dNTPs, each at 0.2 mM. The PCR expansion employs 55 cycles using a thermocycler with 65 seconds melt at 92°C and a 10 min annealing and extension time at 65°C. The two priming oligonucleotides are TGGCGGACCGCTATCCCCCAGGAC and TAGCCTGGGTCCCTCCTTAC, which correspond respectively to a region 650 bases 3' of the start codon of the neomycin gene and sequences located in the mouse heavy chain gene, 1100 bases 3' of the insertion site. 20  $\mu$ l of the reaction mix is electrophoresed on agarose gels and transferred to nylon membranes (Zeta Bind). Filters are probed with a <sup>32</sup>P-labelled fragment of the 991 bp XbaI fragment of the J-C region.

## EXAMPLE II

### II. Deletion of the mouse Ig heavy chain J (J<sub>H</sub>) genes in ES cells

#### A. Construction of the replacement targeting vector

A 6.1-Kb EcoRI fragment, containing the mouse immunoglobulin heavy chain J region genes and flanking sequences, cloned from a BALB/c mouse embryo genomic library and inserted into pUC18 (pJ<sub>H</sub>), was digested with XhoI and NaeI to delete an about 2.3 kb fragment containing the four J genes (see Figure 2A). An about 1.1 kb XhoI-BamHI fragment, blunted at the BamHI site, containing a neomycin resistance gene driven by the Herpes simplex virus thymidine kinase gene (HSV-tk) promoter and polyoma enhancer was isolated from pMC1Neo (Thomas and Capecchi (1987), Cell, 51, 503-512). This fragment was inserted into the XhoI-NaeI deleted pJH to form the deletion vector (pmH $\delta$ J, see Figure 2B), in which the transcriptional orientation of the neomycin and the heavy chain genes is the same. This plasmid was linearized by NdeI digestion before transfection to ES cells. The sequences driving the homologous recombination event are

about 2.8 kb and about 1.1 kb fragments, located 5' and 3' to the neomycin gene, respectively.

B. Culturing, Electroporation, and Selection of ES cells

5           The ES cell line E14TG2a (Koller and Smithies (1989),  
PNAS USA, 86:8932-8935) was cultured on mitomycin C-  
treated embryonic fibroblast feeder layers as described  
(Koller and Smithies (1989), PNAS USA, 86:8932-8935).  
ES cells were trypsinized, resuspended in HBS buffer (pH  
10   7.05; 137 mM NaCl, 5 mM KCl, 2 mM CaCl<sub>2</sub>, 0.7 mM Na<sub>2</sub>HPO<sub>4</sub>,  
21 mM HEPES pH 7.1) at a concentration of 2x10<sup>7</sup>/ml and  
electroporated in the presence of 50 µg/ml of the  
linearized inactivation vector. Electroporation was  
carried out with a BioRad Gene Pulser using 240 volts and  
15   500 µF capacitance. 5x10<sup>6</sup> electroporated cells were plated  
onto mitomycin C-treated fibroblasts in 100 mm dishes in  
the presence of Dulbecco's modified Eagle's media (DMEM)  
supplemented with 15% fetal bovine serum and 0.1 mM 2-  
mercaptoethanol. The media was replaced 24 hr after  
20   electroporation with media containing 200 µg/ml G418.  
G418-resistant ES colonies resulting from growth 12-14  
days after electroporation were picked with drawn out  
capillary pipettes for analysis using the polymerase chain  
reaction (PCR). Half of each picked colony was  
25   transferred to an individual well of a 24-well plate,  
already seeded with mitomycin C-treated feeder cells.  
The other halves, combined in pools of four, were  
transferred to Eppendorf tubes containing 0.3 ml of PBS  
and cell lysates were prepared for PCR analysis as  
30   described by Joyner et al (1989) Nature, 338:153-155.  
The PCR reaction included 5-20 µl of the cell lysate, 1  
µM of each primer, 1.5 U of Taq polymerase and 200 µM of  
dNTPs. The PCR amplification employed 45 cycles using  
a thermal cycler (Perkin-Elmer Cetus), with 1 min. melt  
35   at 94°C, 2 min. annealing at 55°C, and 3 min. extension  
at 72°C. The two priming oligonucleotides are  
ACGGTATCGCCGCTCCCGAT and AGTCACTGTAAAGACTTCGGGTA, which

correspond respectively to about 120 bases 5' of the BamHI site of the neomycin gene, and to the sequences located in the mouse heavy chain gene, about 160 bases 3' of the insertion site. Successful homologous recombination gives rise to an about 1.4 kb fragment. 20 µl of the reaction mixture is electrophoresed on 1% agarose gels, stained with ethidium bromide and transferred to nylon membranes (Gene Screen). Filters were probed with a <sup>32</sup>P-labelled EcoRI-PstI about 1.4 kb fragment located in the mouse heavy chain, 3' of the insertion site (see Figure 2). For further analysis, genomic DNA was prepared from ES cells, digested with restriction enzymes as recommended by the manufacturers, and fragment were separated on 1% agarose gels. DNA was transferred to nylon membranes (Gene Screen) and probed with the <sup>32</sup>P-labelled fragment as described above.

#### C. Analysis of G418-resistant ES colonies

In the first experiment, PCR analysis of the pooled colonies detected one positive PCR signal of the expected size, (about 1.4 kb) out of 34 pools representing 136 G418-resistant colonies. The four individual colonies that had contributed to this positive pool were analyzed individually by PCR, and a positive clone, ES33D5, was identified. Similar analysis of 540 G418-resistant colonies obtained in the second experiment yielded 4 additional positive clones (ES41-1, ES61-1, ES65-1, ES110-1).

In order to verify the targeted disruption of one copy of the J genes, (the gene is autosomal and thus present in two copies), the PCR positive clones were expanded and genomic DNA was prepared, digested with HindIII or with SacI and analyzed by Southern analysis as described using the EcoRI-PstI probe.

The replacement of the J genes by insertion of the neomycin gene by an homologous recombination event results in a HindIII fragment, detectable with the EcoRI-PstI

probe, which is about 1.9 kb longer than the equivalent fragment in the native locus, due to the loss of two HindIII sites located in the deleted J gene region (see Figure 2C). Southern analysis of each of the 5 positive clones by HindIII digestion gave a pattern which indicated that one of the two copies of the heavy chain J genes had been disrupted. Three labelled fragments were detected: one fragment (about 760 bp), identical in size to that present in untreated cells at the same intensity, one fragment (about 2.3 kb) identical in size to that present in untreated cells, but of decreased intensity in the PCR positive clone, and an additional fragment about 4.2 kb, the size predicted for an homologous recombination event, present only in the PCR-positive clones. Similarly, the replacement of the J genes by the neomycin gene by an homologous recombination event results in a loss of one SacI site and the appearance of a fragment, detectable with the EcoRI-PstI probe, which is about 570 bp smaller than the equivalent fragment in the native locus (see Figure 2C). Southern analysis of the clones by SacI digestion gave the expected pattern of one native and one targeted allele: about 4.0 kb fragment, identical in size to that detected in untreated cells, but of decreased intensity in the 5 positive clones, and an additional fragment of about 3.4 kb, the size predicted for a targeted homologous recombination event, present only in the identified clones. Rehybridization of the Southern blots with a probe for the neomycin gene showed that only the 4.2 kb and 3.4 kb fragments, resulting from the HindIII and the SacI digestion, respectively, hybridized to the probe as predicted by the targeting event.

#### D. Generation of chimeric mice with J<sub>H</sub> deletions

Three and a half day old C57BL/6J (Jackson Laboratories, Bar Harbor, ME) blastocysts were obtained from 4-5 week old superovulated females as described by Koller, et al. 1989 (supra). ES cells were trypsinized,

washed once with fresh DMEM media, and diluted to about  $1 \times 10^6$ /ml in DMEM medium containing 10% fetal bovine serum and 20 mM HEPES, pH 7.5. 10 to 15 cells were injected into the blastocoel of each blastocyst. ES-cell  
5 containing blastocysts were then surgically transferred to one uterine horn of C57BL/6J X DBA/2 or C57BL/6J X CBA F1 pseudopregnant females.

The contribution of ES cells to the offspring was judged visually by examination of the coat color of the  
10 pups. C57BL/6J mice are solid black in color. The ES cell parent line E14TG2a was isolated from 129/Ola embryos, which carry three coat color genes, the dominant  $A^W$  allele at the agouti locus, the recessive pink-eyes-dilute allele at the p locus, and the recessive  $C^{ch}$  at the  
15 c locus. Chimeric offspring in which the ES cells participated in the formation of the animal have coats containing agouti and cream hairs.

Germline transmission ability of the chimeric mice was evaluated by mating with a C57BL/6J mouse and scoring  
20 for F1 offspring with agouti color. 50% of these agouti mice would be expected to inherit the mutated heavy chain allele, which can be identified by Southern blot analysis of DNA isolated from tails.

The  $J_H$ -targeted ES cell line ES65-1, carrying one  
25 targeted heavy chain allele, was injected into C57BL/6J mouse blastocysts. About 45% of the surviving pups were chimeras. Two chimeric females, 238-2 and 244-3, upon mating with C57BL/6J males, yielded germline transmission at a frequency of 100% and 15%, as determined by the  
30 percent of agouti offspring. Southern blot analysis of DNA from heterozygous offspring indicated the presence of the targeted heavy chain in addition to one native allele in 2 out of 5 agouti progeny tested.

Mice homozygous for the mutation were obtained by  
35 intercrossing male and female mice which were identified as  $J_H$ -deleted ( $\delta J_H$ ) heterozygotes. Offspring of these

matings were analyzed for the presence of the two targeted heavy chain alleles by Southern blot analysis.

E. Analysis of B cells from chimeric mice

5           If deletion of the  $J_H$  region is sufficient to inactivate the heavy chain locus, then it should result in complete block of development of IgM-expressing B cells and of antibody production. Mice which are heterozygous at the  $J_H$  locus carry one intact and functional heavy chain allele, derived from the C57BL/6J parent, and one  $J_H$ -deleted heavy chain allele which is derived from the ES cells (129/Ola strain). The 129 and B6 strains differ in Ig heavy chain allotypes. The ES-derived B cells (IgM<sup>a</sup> allotype) can be distinguished from B6-derived B cells (IgM<sup>b</sup> allotype) with allotype-specific monoclonal antibodies, using flow cytometry analysis of antibody expressing B.

10           The specificity of these antibodies is shown in Figure 3 (A-C). Peripheral blood lymphocytes were stained with antibodies to the B cell specific marker, B220, and with antibodies to the IgM allotype. B cells from C57BL/6J mice stained with antibodies directed against the IgM<sup>b</sup> allotype but not the IgM<sup>a</sup> allotype (Figure 3B). B cells derived from 129/Ola mice stained with antibody against the IgM<sup>a</sup> allotype, but not the IgM<sup>b</sup> allotype (Figure 3A). In heterozygous (a/b F1) mice carrying one intact ES-derived heavy chain allele and one intact C57BL/6J-derived heavy chain allele, both allotypes were present in equal amounts (Figure 3C).

15           When B cells from mice which were heterozygous for the  $J_H$  deletion were analyzed, where the  $J_H$  deleted heavy chain allele was from the 129/Ola parent, there were no cells positive for the IgM<sup>a</sup> allotype. All B cells were IgM<sup>b</sup> positive, from the intact C57BL/6J heavy chain allele (Figure 3D). These results indicated that the  $J_H$ -deleted heavy chain locus is inactivated and cannot encode a functional IgM antibody.

Mice which were homozygous for the J<sub>H</sub> deletion were also analyzed for the ability to produce functional antibodies. Peripheral blood lymphocytes from homozygous mutant mice were analyzed by flow cytometry, using antibodies to the B cell specific marker B220, and with the allotype specific markers (see Figure 4). In contrast to the control mice (Figure 4D-F), no B220<sup>+</sup> cells, or IgM producing cells could be detected in the mutant mice (Figure 4A-C). In addition, the mutant mice had no detectable IgM in the serum. These results indicate that the deletion of the J<sub>H</sub> region from both heavy chain alleles leads to complete inhibition of B cell development to mature B cells and production of antibody.

#### F. Generation of homozygous mutant ES cells

The effect of J<sub>H</sub> deletion on B cells can also be analyzed by generating ES cells with both heavy chain alleles targeted, which are then used to produce chimeric mice which contain a population of lymphoid cells homozygous for the mutation.

Homozygous  $\delta$ J<sub>H</sub> mutant ES cells were generated by subjecting one of the heterozygous mutant ES clones, ES110-1, to elevated levels of G418 (1.4 mg/ml) thus selecting for homogenotization of the targeted allele. Seven of the surviving colonies were screened by Southern blot analysis using SacI digestion for the loss of the wild-type heavy chain allele and acquisition of a second targeted allele. One of these clones, ESDK207 was shown to have lost the native heavy chain allele, as evidenced by the inability of probes to detect the wild type 4.0 kb fragment and by the increased intensity of the 3.4 kb targeted fragment. Karyotypic analysis of ESDK207 indicated that, like the parent line ES110-1, about 80% of the cells had 40 chromosomes, suggesting that two targeted alleles were present. The homozygous mutant ES cells were microinjected into C57BL/6J blastocysts and chimeric mice were generated.

G. Analysis of B cells from homozygous chimeras

B cells from chimeric mice were analyzed to determine the effect of J<sub>H</sub> deletion on B cell development and antibody production. Lymphocytes from the ES cell line (129/Ola) can be distinguished from blastocyst-derived (C57BL/6J) lymphocytes by a monoclonal antibody to the Ly-9.1 marker, which is found on lymphocytes of 129 origin, but not those of B6 origin. In addition, the two strains differ in their IgM allotype, as previously described.

The chimeras analyzed had been derived from wild-type E14TG2a ES cells (WT), or from ES cells that were heterozygous (ES110-1, ES65-1) or homozygous (ESDK207) at the targeted J<sub>H</sub> region. Peripheral blood mononuclear cells were stained with antibodies to the B cell specific marker B220, and with antibodies to either Ly-9.1 or IgM allotypes, and then analyzed by two-color flow cytometry. To evaluate chimerism in the T cell lineage, the cells were stained with antibody for the T cell marker Thy 1.2, and with anti-Ly-9.1 antibody. Staining of cells from the parental mouse strains provided controls for the specificity and sensitivity of the assay.

Mice with similar degrees of chimerism, as judged by coat color, were compared. ES-derived B and T cells were detected in the peripheral blood of chimeric mice generated from the wild-type E14TG2a ES cells, confirming the ability of this cell line to give rise to lymphoid cells in vivo. Analysis of chimeras generated from single J<sub>H</sub>-targeted ES65-1 and ES110-1 cells demonstrated the presence of B220<sup>+</sup>/IgM<sup>+</sup>/Ly-9.1<sup>+</sup> B cells containing a single, intact, ES cell-derived Ig heavy chain locus.

In contrast to the WT and single deletion chimeras, mice generated from the homozygous mutant ESDK207 cell line lacked Ly-9.1<sup>+</sup>/B220<sup>+</sup> or IgM<sup>+</sup>/B220<sup>+</sup> B cells in peripheral blood. The observed lack of ESDK207-derived B cells was not due to a lack in lymphopoiesis, since ES-derived Ly-9.1<sup>+</sup>/B220<sup>+</sup> cells represented 12% of the total

pool of peripheral blood mononuclear cells. Of these, approximately half were Thy-1.2<sup>+</sup> T cells. Thus, deletion of the J<sub>H</sub> region from both alleles blocks development of mature IgM<sup>+</sup> producing B cells. Similar observations were made for chimeric spleen cells.

Chimeras were also tested for the presence of serum IgM derived from the ES cells. IgM<sup>+</sup> levels were high in chimeras from wild-type ES cells and cells with a single targeted mutation, but were undetectable in mice derived from the ESDK207 cell line.

Further analysis showed that the bone marrow of ESDK207 mice contained normal IgM<sup>b+</sup> B cells derived from the blastocyst host, but lacked ES-derived IgM<sup>+</sup> B cells. However, DK207-derived bone marrow did contain a population of cells which were B220<sup>dim</sup>/Ly-9.1<sup>+</sup> derived from the ES cells. The bone marrow is therefore likely to contain a subpopulation of ES cell-derived B cell precursors, whose maturation is blocked by the homozygous deletion of the J<sub>H</sub> region.

The bone marrow cells were also analyzed with three-color flow cytometry, using antibodies to Ly-9.1, B220 and either CD43 or Thy-1.2. The results show the majority of ES-derived cells were CD43 positive, which is consistent with an early block in maturation. Many of the cells were also positive for Thy-1.2, as would be expected of very early B cell precursors. These data show that deleting the J<sub>H</sub> region results in the inability of the heavy chain locus to rearrange and produce functional IgM. Lack of IgH rearrangement results in a block of B cell maturation, restricting B cell progenitors to an early stage of development.

EXAMPLE IIIDeletion of the Mouse Ig kappa light chain constant  
(C<sub>k</sub>) region5     A. Construction of the replacement targeting vector

The kappa region was inactivated with a replacement type vector, which was designed to delete the constant region of the kappa locus, and replace it with the G418 drug resistance marker through homologous recombination. Homologous recombination was driven by regions of homology which flank the constant region (see Figure 5).

A genomic library from 129/Ola mouse fetal liver DNA (Stratagene) cloned into lambda phage was screened for the presence of the mouse C<sub>k</sub> gene with a 1.6 kb HpaI/BamHI fragment (Steinmetz and Zachau (1980) Nucleic Acids Research 8:1693-1706) that spans the mouse kappa constant region. A lambda phage clone which hybridized to this probe was identified, then purified and used as a source of C<sub>k</sub> DNA. Analysis of the phage DNA showed that the kappa constant region probe hybridized to a 5.6 kb SphI/BamHI fragment. This fragment contained the kappa J region genes, an intronic enhancer element and the kappa constant region. It was then isolated and subcloned into the SphI and BamHI sites of the plasmid pUC218 to give the plasmid pUC218/5.6kappa.

In order to construct the deletion vector, fragments containing the 5' region of the kappa constant region, a thymidine kinase gene for negative selection, a neomycin resistance gene and a 3' region of homology to the kappa constant region were ligated together (see Figure 6).

A 4.0 kb SphI/Bsu361 fragment from the plasmid pUC218/5.6kappa was subcloned into the SphI and Bsu361 sites of the vector pSK.A to give the plasmid pSK.A/5'K. The vector pSK.A is a modification of pBluescript SK- which has a synthetic polylinker:

5' GCATATGCCTGAGGTAAGCATGCGGTACCGAATTCTATAAGCTTGC GGCCG CAGCT  
CATGCGTATACGGACTCCATTTCGTACGCCATGGCTTAAGATATTCGAACGCCGGCG 3'

inserted between the pBluescript KpnI and SacI sites.

A 2.7 kb EcoRI/HindIII fragment containing the herpes thymidine kinase (TK) gene driven by the mouse phosphoglycerate kinase gene (PGK) promoter from the plasmid pKJtk (Tybulewicz, et al. (1991) Cell 65:1153-1163) was inserted into the EcoRI and NotI sites of pSK.A/5'K by using a HindIII/NotI adapter with the sequence:

5' AGCTGGAACCCCTTGCCCTTGGGGAACGCCGG 3'.

In the resulting plasmid, pSK.A/5'K/TK; the 5' end of the TK gene and the kappa constant region gene are adjacent to each other, in opposite transcriptional orientations.

A 1.1 kb XhoI/BamHI fragment from pMC1Neo, which contains the mammalian drug selectable marker for resistance to neomycin, was cloned into the XhoI and BamHI sites of the plasmid pSK.B to give the plasmid pSK.B/Neo. The vector pSK.B is a modification of pBluescript SK- which has a synthetic polylinker:

5' GAGCTCGGATCCTATCTCGAGGAATTCATAAGCTTCATATGCTAGCT  
CATGCTCGAGCCTAGGATAGAGCTCCTTAAGATATTCGAAAGTATACA 3'

inserted between the pBluescript KpnI and SacI sites.

A 1.1 kb BglII/BamHI fragment from pUC218/5.6kappa, which contains homology to the 3' end of the kappa region, was cloned into BamHI digested, alkaline phosphatase treated pSK.C vector. The vector pSK.C is a modification of pBluescript SK- which has a synthetic polylinker:

5' AAGCTTATAGAAATTCGGTACCTGGATCCTGAGCTCATAGCGGCCGAGCT  
CATGTTGGAATATCTTAAGCCATGGACCTAGGACTCGAGTATCGCCGGCG 3'

inserted between the pBluescript KpnI and SacI sites.

The resulting plasmid, pSK.C/3'K is oriented such that transcription proceeds from the SacI site in the plasmid polylinker in the direction of the KpnI site.

The final targeting plasmid was constructed with a three part ligation, using (A) 6.1 kb NotI/NdeI fragment from pSK.A/5'K/TK, (B) 1.2 kb NdeI/SacI fragment from pSK.B/Neo and (C) 4.0 kb SacI/NotI fragment from pSK.C/3'K ligated to make the plasmid pK.TK/neo.

B. Electroporation of kappa deletion vector into ES cells

Purified plasmid DNA from pK.TK/Neo was cut with PvuI, extracted with phenol/chloroform and ethanol precipitated. The DNA was resuspended after precipitation at a concentration of 1 mg/ml in 10 mM Tris-HCl, 1 mM EDTA.

The embryonic stem cell line E14-1, a subclone of E14 (Hooper, et al. (1987) Nature 326:292-295) was cultured in DMEM 4.5 g/l glucose (J.R.H. Biosciences) supplemented with 15% heat inactivated fetal calf serum, recombinant murine leukemia inhibitory factor (ESGRO from Gibco BRL, 1000 U/ml), 0.1 mM  $\beta$ -mercaptoethanol, 2 mM glutamine and 100 U/ml penicillin at 37° C in 5% CO<sub>2</sub>.

The cells were cultured on mitomycin-treated primary embryonic fibroblast feeder layers essentially as described (Koller and Smithies (1989) supra). The embryonic fibroblasts were prepared from day 14 embryos carrying the homozygous targeted mutation of  $\beta$ 2-microglobulin (Koller and Smithies (1990) Science 248:1227-1230). These feeder cells are capable of growth in media containing G418.

At 80% confluency, the ES cells were prepared for electroporation by trypsinization, concentration by brief centrifugation and resuspension in HEPES-buffered saline at  $2 \times 10^7$  cells/ml. The cells are equilibrated at room temperature, and linearized targeting vector DNA (20  $\mu$ g) added. The mixture was electroporated at 960  $\mu$ F and 250 V with a BioRad Gene Pulser. The cells were left to stand at room temperature for 10 minutes before plating onto 4 x 10 cm dishes of mitomycin-treated fibroblast feeders ( $3 \times 10^6$  feeder cells/plate). After incubation at 37° C for 48 hours, the cells were fed media containing 150  $\mu$ g/ml G418 to select for neomycin resistance. After a further 48 hours the cells were fed media containing 150  $\mu$ g/ml G418 and 2  $\mu$ M gancyclovir (Syntex) to select for loss of the thymidine kinase gene.

C. Analysis of targeted ES cells

After ten days of drug selection with both G418 and gancyclovir, the individual surviving colonies were picked and dissociated with a drop of trypsin in a 96 well plate, then incubated at 37° for 2 minutes. The cells from each colony were transferred into a well of a 24-well plate containing mitomycin C-treated feeder cells and selective media with G418, but not gancyclovir. After an additional 5-8 days, 20% of the cells in each well were frozen, and the remainder used to prepare genomic DNA. The cells were lysed with 0.4 ml of 10 mM Tris-HCl (pH 7.5), 100 mM NaCl, 10 mM EDTA, 1% SDS and proteinase K (1 mg/ml) by overnight incubation at 50° C. The DNA was purified by phenol extraction and ethanol precipitation, then washed with 70% ethanol and resuspended in 20 µl of 10 mM Tris-HCl, 1 mM EDTA.

Southern analysis was carried out using BglII digested genomic DNA from each sample. An about 1.2 kb BamHI/BglII fragment which contains the region contiguous with the 3' homology fragment in the targeting vector was used as a probe. The native ES cell locus gave an about 2.3 kb fragment, while the targeted ES cell locus gave an about 5.7 kb fragment. The increase in size is due to the loss of a BglII site during the construction of the deletion vector.

A Southern analysis of 166 clones showed two cell lines which had the intended mutation. These clones were further analyzed by reprobing the filters with an about 1.1 kb fragment which spans the neo gene. As expected, the probe only hybridized to the targeted allele.

Further analysis of the genomic DNA from the two positive clones, 1L2-850 and 1L2-972, after being thawed and expanded, reconfirmed the initial observations. A third probe, an about 1.7 kb HindIII/BglII fragment spanning the kappa J region locus, was used to check for the correct integration pattern from the 5' end of the targeting vector. Using this probe with EcoRI digested

genomic DNA, an about 15 kb fragment is detected in the native allele, and an about 5 kb fragment from the targeted locus. The additional EcoRI site is introduced by the neo gene during homologous recombination targeting (see Figure 7).

#### D. Generation of germline chimeras

The unmodified E14-1 cells have been found to contribute to the germline at a high frequency after injection into C57BL/6J blastocysts. To generate germline chimeras containing the targeted kappa region, the targeted cell lines 1L2-850 and 1L2-972 were grown on primary feeder cells, then trypsinized and resuspended in injection medium, which consists of DMEM supplemented with 15% fetal calf serum, 20 mM HEPES (pH 7.3), antibiotics and  $\beta$ -mercaptoethanol. The ES cells were injected into each blastocyst, and the injected blastocysts then transferred to one uterine horn of a pseudopregnant female mouse. Chimeric pups were identified by chimeric coat color. Chimeric males were bred to C57BL/6J females, and germline transmission of the 129/Ola derived ES cells was detected by agouti coat color of the offspring.

One chimeric male from cell line 1L2-972 (about 40% ES cell derived as judged by its coat color), upon mating with C57BL/6J females yielded germline transmission at a frequency of 25% as determined by the percent of agouti offspring. Chimeric males, about 40%, 70% and 90% chimeric, from cell line 1L2-850 yielded germline transmission at a frequencies of 90%, 63% and 33%, respectively. Among the agouti offspring generated from the 70% chimeric male from 1L2-850, eight F1 animals out of 12 tested were found to be heterozygous at the kappa locus for the targeted  $C_k$  mutation by Southern analysis (a Bgl II digest using the 1.2 kb Bam HI/Bgl II fragment described above as a probe) using genomic DNA derived from tail samples. Further breeding of a male and female from

this group of 8 F1 animals, both heterozygous for the  $C_k$  mutation, yielded one male offspring found to be homozygous for this mutation as confirmed by Southern analysis.

5

E. Analysis of B cells obtained from mice targeted at the kappa locus

If the kappa ( $\kappa$ ) light chain locus is inactivated because of deletion of the light chain constant region ( $C_k$ ), the joining region ( $J_k$ ), or both  $C_k$  and  $J_k$ , then a complete block in the development of  $\kappa$ -expressing B cells should result. Mouse embryonic stem cells containing a single copy of the complete  $C_k$  deletion ( $\Delta C_k$ ) were introduced into mouse blastocysts as described above to produce chimeric mice. These chimeric mice were then bred with wild-type C57BL/6 (B6) mice, and the F1 progeny were assayed for the presence of the  $\Delta C_k$  mutation by Southern blotting of tail DNA. F1 mice that carried the  $\Delta C_k$  mutation were bred and F2 offspring were assayed similarly for  $\Delta C_k$ . One of 5 F2 offspring was shown to carry a homozygous  $C_k$  deletion, and another was heterozygous, bearing both  $\Delta C_k$  and a wild-type  $C_k$  allele. The 3 other offspring were wild-type. The presence or absence of  $\kappa$ -positive B cells was assayed by flow cytometric analysis of peripheral blood B cells stained with fluorescent antibodies that react with a pan-B cell marker (B220) or with the  $\kappa$  light chain. For the homozygous  $\Delta C_k$  F2 mouse no  $\kappa$ -positive B cells were detected, and in the heterozygote, there was a reduction in the frequency of  $\kappa$  positive B cells, consistent with the presence of a wild-type allele and a non-functional  $\Delta C_k$  allele. These results demonstrate that deletion of  $C_k$  from the chromosome prevents  $\kappa$  expression by mouse B cells.

35

EXAMPLE IV

Inactivation of the mouse immunoglobulin kappa light chain  
J and constant region

5     A. Design of the targeting experiment

          The targeting vector was designed as a replacement  
type vector initially to delete the constant region as  
well as the J region of the kappa locus and replace it  
10     with three elements through homologous recombination using  
regions of homology flanking the constant region (Figure  
8). A diphtheria toxin gene (A chain) flanking either  
or both regions of homology was included in some cases  
as a negative selectable marker. The three elements  
15     consisted of the G418 resistance drug marker, an  
additional DNA homology (ADH) sequence of mouse DNA  
homologous to a region of the kappa locus located upstream  
of the J region, and a thymidine kinase gene. As a result  
of the inclusion of the ADH sequence in the vector, this  
20     initial targeting placed a second copy of the ADH in the  
locus. This duplication was then used to effect a defined  
deletion of the sequences between the segments by applying  
selective pressure. In this case the cell deletes the  
thymidine kinase gene that lies between the two segments  
25     in order to survive gancyclovir selection.

B. Construction of the targeting vector

          The regions of homology were derived from a 129 mouse  
fetal liver genomic library (Stratagene) which was  
30     screened using two probes, as described above in Example  
III. This subclone contained the J region, an intronic  
enhancer element and the constant region of the kappa  
light chain locus. The second probe was a 0.8 kb EcoRI  
fragment (Van Ness et al. (1981), Cell 27:593-602) that  
35     lies 2.8 kb upstream of the J region. Phage DNA from a  
lambda clone positive for this probe showed that the probe  
hybridized to a 5.5 kb SacI fragment which was subcloned  
into the SacI site of pBluescript SK<sup>-</sup> (Stratagene) to give  
the plasmid pSK.5'kappa (Figure 8).

The inactivation vectors which contained a 5' region of homology, a thymidine kinase gene, a ADH, a neomycin resistance gene and a 3' region of homology (Figure 9) flanked in some instances by diphtheria toxin genes were constructed from three plasmids (Figure 8) containing:

5 (a) the 5' fragment of homology with or without the diphtheria toxin gene (DT) driven by the mouse phosphoglycerate kinase gene (PGK) promoter as a negative selectable marker, (b) the herpes thymidine kinase gene

10 (tk) driven by the mouse phosphoglycerate kinase gene (PGK) promoter as a negative selectable marker along with the DSH and the G418 selectable neomycin (neo) gene from pMC1Neo (Thomas and Capecchi (1987), Cell 51:503-12), and

15 (c) the 3' fragment of homology with or without the PGK driven DT gene. These three plasmids (Figure 8) were constructed from pSK.A, pSK.B, and pSK.C, respectively, all derived from the plasmid pBluescript SK<sup>-</sup> by modification of the polylinker.

The polylinker of the plasmid pBluescript SK<sup>-</sup> was modified by cloning between the KpnI and SacI sites a synthetic polylinker defined by the oligonucleotides 5'-GCATATGCCTGAGGGTAAGCATGCGGTACCGAATTCTATAAGCTTGCGGCCGCAGCT-3' AND 5'-GCGGCCGCAAGCTTATAGAATTCGGTACCGCATGCTTACCTCAGGCATATGCGTAC-3' to create the plasmid

20 pSK.A, 5'-GAGCTCGGATCCTATCTCGAGGAATTCTATAAGCTTCATATGTAGCT-3' and 5'-ACATATGAAGCTTATAGAATTCCTCGAGATAGGATCCHA

25 GCTCGTAC-3' to create plasmid pSK.B, 5'-AAGCTTATAGAATTCGGTACC TGGATCCTGAGCTCATAGCGGCCGCAGCT-3' to create plasmid pSK.B and 5'-GCGGCCGCTATGAGCTCAGGATCCAGGTACCGAATTCTATAAGCTTG TAC-3' to create the plasmid pSK.C.

A diphtheria toxin gene cassette was created in which the gene was flanked by the PGK promoter and the bovine growth hormone polyadenylation signal (Woychik et al. (1984), Proc. Natl. Acad. Sci. U.S.A., 81:3944-3948; Pfarr et al. (1986), DNA 5:115-122). A 2.3 kb XbaI/EcoRI fragment from pTH-1 (Maxwell et al. (1986), Cancer Res.

35

46:4660-4664) containing the diphtheria toxin A chain driven by the human metallothionein (hMTII) promoter was cloned into pBluescript SK<sup>-</sup> cut with XbaI and EcoRI to give the plasmid pSK.DT. The hMTII promoter of pSK.DT was replaced with the PGK promoter from pKJ1 (Tybulewicz et al. (1991), Cell 65:1153-1163). A 0.5 kb XbaI/PstI fragment from pKJ1 was joined to a 3.1 kb XbaI/NcoI fragment from pSK.DT using a PstI/NcoI adapter formed from the oligonucleotides 5'-GGGAAGCCGCCG-3' and 5'-CATGGC GGCGGCTTCCCTGCA-3' to give the plasmid pSK.pgkDT. A 248 bp fragment containing the bovine growth hormone polyadenylation signal, obtained by PCR amplification of bovine genomic DNA using the oligonucleotide primers 5'-CAGGATCCAGCTGTGCCTTCTAGTTG-3' and 5'-CTGAGCTCTAGACCCATA GAGCCCACCGCA-3', was cloned into PCR1000 (Invitron Corp., San Diego, CA). The polyadenylation sequence was then cloned behind the DT gene as a HindIII/PvuII fragment into pSK.pgkDT cut with HindIII and HpaI to give the plasmid pSK.pgkDTbovGH. The DT gene cassette from pSK.pgkDTbovGH was moved as a 2.1 kb EcoRI/HindIII fragment into pSK.A cut with EcoRI and NotI using a HindIII/NotI adapter formed from the oligonucleotides 5'-AGCTGGAACCCCTTGC-3' and 5'-GGCCGCAAGGGGTTC-3' to give the plasmid pSK.A/DT. Between the SphI and Bsu36I sites of both pSK.A and pSK.A/DT the 5' region of homology for the kappa locus was cloned. For this purpose a 4.0 kb SphI/Bsu36I fragment resulting from a partial Bsu36I digest followed by a complete SphI digest of plasmid subclone pUC218/5.6kappa was ligated to pSK.A or pSK.A/DT to give the plasmids pSK.A/5'K and pSK.A/DT/5'K, respectively. In the plasmid, pSK.A/DT/5'K, the 5'-end of the DT gene and kappa fragment were adjacent to each other running in the opposite transcriptional orientations.

The PGKtk gene from the plasmid pKJtk (Tybulewicz et al. (1991), Cell 65:1153-1163) was cloned as a 2.7 kb EcoRI/HindIII between the unique EcoRI and HindIII sites of pSK.B to give pSK.B/TK. A 0.8 kb EcoRI fragment used

for the ADH was cloned from pSK.5'kappa and was ligated into the EcoRI site of pSK.B/TK to give pSK.B/(TK/0.8K) such that the 5'-end of the tk gene and kappa fragment were adjacent to each other running in opposite transcriptional orientations. The 1.1 kb neo gene from pMC1Neo was cloned as an XhoI/BamHI fragment between the same sites of pSK.B/(TK/0.8K) to give pSK.B/(TK/0.8K/Neo). The plasmid pSK.C/3'K containing the 3' fragment of homology was constructed by ligating pSK.C digested with BamHI and treated with alkaline phosphatase to the 1.1 kb BglIII/BamHI fragment isolated from pUC218/5.6kappa. In pSK.C/3'K, the kappa fragment was oriented such that transcription proceeded from the SacI in the plasmid polylinker in the direction of the KpnI site. The 2.1 kb DT cassette from pSK.pgkDTbovGH was cloned as an EcoRI/HindIII fragment into the same sites of pSK.C to give pSK.C/3'K/DT.

Three-part ligations were carried out to construct the final targeting plasmids (Figure 9). The 4.0 kb NotI/NdeI fragment from pSK.A/5'K, the 4.8 kb NdeI/SacI fragment from pSK.B/(TK/0.8K/Neo) (obtained by a SacI partial followed by and NdeI digestion of the plasmid), and the 4.0 kb SacI/NotI fragment from pSK.C/3'K were isolated and ligated together to create pK.(TK/0.8K/Neo). The 6.1 kb NotI/NdeI fragment from pSK.A/DT/5'K, the 4.8 kb NdeI/SacI fragment from pSK.B/(TK/0.8K/Neo), and 4.0 kb SacI/NotI fragment from pSK.C/3'K were isolated and ligated together to create pK.DT/(TK/0.8K/Neo). The 6.1 kb NotI/NdeI fragment from pSK.A/DT/5'K, the 4.8 kb NdeI/SacI fragment from pSK.B/(TK/0.8K/Neo), and 6.1 kb SacI/NotI fragment from pSK.C/3'K/DT (obtained by a SacI partial followed by a NotI digestion of the plasmid) were isolated and ligate together to create pK.DT/(TK/0.8K/Neo)/DT. For electroporation, the purified plasmid DNAs were first cut with PvuI or ApaLI, then extracted with phenol/chloroform and precipitated by the addition of ethanol before centrifugation. The resultant
